Abstract

The one-dimensional (1D) t - J model is investigated by using a Gutzwiller-Jastrow-type variation method and the exact diagonalization of small systems. Variational expectation values are estimated by the variational Monte Carlo method with sufficient accuracy. First, we represent the diagonalization results. Physical quantities like momentum distribution and some correlation functions show some behaviors which are not expected in repulsive models, as the value of J/t increases. These properties as well as energy are well understood by introducing intersite correlation factors into wave functions. The phase transition to a separated phase in large- J/t region can be described by an attractive Jastrow wave function in quantitative agreement with the exact results. On the other hand, for the supersymmetric case ($J/t = 2$) the original Gutzwiller wave function becomes an extremely good trial function for all the range of electron density. Here a kind of “free electron” state is realized, particularly in the low electron density. Next, the above wave functions are compared with the Tomonaga-Luttinger-liquid-type wave function proposed by Hellberg and Mele. It is found that the correlation factors in short distances control bulk quantities like energy and the magnitude of correlation functions, while the long-range part of correlation factors determines the critical behavior of correlation functions. Lastly, using these functions, charge and spin susceptibilities and magnetization curve are estimated, which agree with the exact results. It is shown that the Mott transition in 1D t - J model is quite different from the Brinkman-Rice transition.

§1. Introduction

The t - J model is an important model to study highly correlated electron systems for its simplicity and close relationship to the high temperature superconductivity.¹⁾ Many properties in one-dimensional (1D) systems have been clarified extensively by a number of methods: Bethe-Ansatz solutions, g -ology, Tomonaga-Luttinger (TL) liquid theory, quantum Monte Carlo simulations, exact diagonalization studies of small clusters, and conformal field theory. We expect that the study of 1D systems will shed light on more realistic higher-dimensional systems and that the comparison of the various methods with the well-established 1D results enables us to judge the validity of such methods and approximations.

In contrast to the 1D Hubbard model,²⁾ the Bethe Ansatz solution does not exist in the 1D t - J model except for $J/t = 0$ (spinless-fermion case) and $J/t = 2$ (supersymmetric case).^{3,4)} In both soluble cases, TL liquid⁵⁾ is realized and the exponents of long-range behaviors of correlation functions were calculated exactly by combining the Bethe Ansatz equations and the conformal field theory.⁶⁻⁹⁾ Also obtained were bulk quantities like spin susceptibility χ_s , charge susceptibility χ_c , specific heat coefficient and effective transport mass, which characterize metal-insulator (Mott) transitions.¹⁰⁾ On the other hand, for general values of J/t , Ogata et al.¹¹⁾ studied the low-lying energy spectrum of finite systems to obtain the correlation exponents. In the phase diagram of J/t and the electron density n , the TL liquid theory holds in the small- J region below $J_c/t = 2.5 \sim 3.5$, depending on n . A phase separation takes place in the larger- J/t ; there is a region in which the superconducting correlation is dominant, between the phase separation and the supersymmetric case.

Meanwhile, as for physical quantities such as momentum distribution function or spin- and charge-correlation functions, only the long-range behaviors were clarified in the above analytic methods; the global features were calculated numerically. In the limit of $J/t \rightarrow 0$, identical with the large- U limit of the Hubbard model, the correlation functions were obtained by taking advantage of the spin-charge separation in the ground state.¹²⁾ For the other values of J/t , Assaad and Würtz¹³⁾ and Imada¹⁴⁾ have carried out quantum Monte Carlo simulations. Pruschke and Shiba¹⁵⁾ studied the superconducting correlation functions by the exact diagonalization. All these results are consistent with the correlation exponents obtained by the analytic methods.

Although the ground-state properties in the 1D t - J model have been clarified quite well, it is still important to examine variational wave functions. For the explicit form of the wave function will make the complicated physics easy to grasp. So far, various kinds of variational states have been proposed for strongly correlated systems.¹⁶⁻²³⁾ The

Gutzwiller wave function (GWF)²⁴⁾ was studied numerically^{16,17)} and analytically.^{18,19)} These studies concluded that the GWF is excellent for the one-dimensional Heisenberg model, but is unsatisfactory, even qualitatively, in describing the properties of the strong coupling Hubbard model or of the small- J region of the t - J model. For example, the GWF does not reproduce the $2k_F$ peak in the spin correlation function; in the momentum distribution, it has a strange enhancement for $k > k_F$. The main reason is that the density correlation is not sufficiently introduced in the GWF, although the spin correlation is well incorporated. These unsatisfactory features are partly remedied by introducing Jastrow-type intersite correlation factors.^{20,22,23)}

In this paper we show that the ground state properties of the 1D t - J model become more easily accessible from a variational viewpoint. First, the behaviors obtained by the exact diagonalization for $J/t = 2$ is described extremely well by the GWF. Next, the wave function is improved for other values of J/t by introducing Jastrow-type wave functions with intersite correlation factors, which are classified into two types: one is the conventional repulsive and attractive Jastrow-correlation factors and the other is a long-range Jastrow factor introduced by Hellberg and Mele.²³⁾ The exponent in the former state is the same as the Fermi liquid, while the latter state has non-trivial exponents. It is found that the long-range behavior of the Jastrow factor is essential for the non-trivial exponent, or non-Fermi liquid behavior. On the other hand, the variational energy and the global features of the correlation functions are modified mainly by the short-range behavior of the Jastrow factor. We also show that quantities like χ_c , χ_s and magnetization curve obtained by the above wave functions are not only qualitatively but quantitatively consistent with the exact results. This aspect is in sharp contrast with the so-called Brinkman-Rice transition.

The outline of this paper is as follows: in §2 we discuss the diagonalization results for various correlation functions as well as the ground-state energy. In §3 the properties of the GWF are studied comparing with those of the exact calculations for the supersymmetric case. Section 4 is devoted to the study of the other values of J/t by introducing Fermi-liquid-type Jastrow wave functions. In §5 another variational state with an essentially long-range Jastrow correlation (TL-liquid-type) is examined and compared with the former type. In §6, χ_c , χ_s and magnetization curve are investigated. Section 7 is assigned to summary. In Appendices A and B, an analytical approach to the GWF used in §3 and the behavior of χ_c and χ_s in the Gutzwiller approximation compared in §6 are summarized respectively. A part of the results in this paper was reported before.^{22,25)}

§2. Ground-State Properties Obtained in Small Clusters

We study the one-dimensional (1D) t - J model defined as

$$\mathcal{H} = \mathcal{H}_t + \mathcal{H}_J, \quad (2.1)$$

$$\mathcal{H}_t = -t \sum_{j\sigma} (c_{j\sigma}^\dagger c_{j+1\sigma} + \text{h.c.}), \quad (2.1a)$$

$$\mathcal{H}_J = J \sum_j (\mathbf{S}_j \cdot \mathbf{S}_{j+1} - \frac{1}{4} n_j n_{j+1}), \quad (2.1b)$$

in the subspace with no double occupancy with $t, J \geq 0$. Spin operators vanish when they are applied to empty sites. Henceforth we take t as the unit of energy.

We use the Lanczos method and the conjugate gradient method²⁶⁾ to obtain the ground-state wave function in small clusters. Figures 1(a)-(c) show the momentum distribution function

$$n(k) = \langle c_{k\sigma}^\dagger c_{k\sigma} \rangle, \quad (2.2)$$

and spin- and charge-correlation functions

$$\begin{aligned} S(k) &= \frac{1}{N_a} \sum_{j,\ell} 4 \langle S_j^z S_\ell^z \rangle e^{ik(r_j - r_\ell)}, \\ N(k) &= \frac{1}{N_a} \sum_{j,\ell} \{ \langle n_j n_\ell \rangle - \langle n_j \rangle \langle n_\ell \rangle \} e^{ik(r_j - r_\ell)}, \end{aligned} \quad (2.3)$$

obtained exactly for various values of J . These results are for the quarter-filled case: $n = N/N_a = 0.5$, with N and N_a being the number of electrons and sites, respectively. As shown in the 1D $U \rightarrow \infty$ Hubbard model,¹²⁾ even the 16-site cluster gives fairly reliable correlation functions. The thermodynamic limit is estimated easily by interpolating the data points for the 16-site cluster except for the singularities. Notice that $S(k)$ and $N(k)$ are also calculated by Assaad and Würtz¹³⁾ using quantum Monte Carlo simulations. Their results agree with Figs. 1(a)-(c).

There are power-law singularities in the momentum distribution $n(k)$ at k_F and $3k_F$. The $3k_F$ singularity is not so prominent in the small systems in Fig. 1(a). The power-law singularity at k_F is the strongest when $J/t = 0$. With increasing J/t , its singularity becomes weaker until $J/t = 2$ where $n(k)$ seems to have a jump at k_F . In the region $J/t > 2$ the power-law singularity shows up again. This dependence on J is consistent with the behavior of the numerically obtained correlation exponent K_ρ which increases from $1/2$ as J increases.¹¹⁾ Here the exponent K_ρ is defined such

that $\langle s_i^z s_j^z \rangle$ decays as $\exp\{2ik_F r_{ij}\}/r_{ij}^{K_\rho+1}$. The exponent at k_F of $n(k)$ is defined as $n(k) = n_0 - C \text{sgn}(k - k_F)|k - k_F|^\alpha$. Since this exponent α is related to K_ρ as $\alpha = (K_\rho + 1/K_\rho - 2)/4$, it starts from $\frac{1}{8}$ at $J/t = 0$, decreases for $0 < J/t < 2$, becomes $\alpha = 0$ near $J/t = 2$ and then begins to increase for $J/t > 2$ where K_ρ becomes larger than 1.

There are $2k_F$ singularities in $S(k)$ and $N(k)$. The TL liquid theory predicts that these singularities have the same correlation exponents K_ρ and that the size-dependence is $A - CN_a^{-K_\rho}$. As seen from Fig. 1, it is difficult to estimate K_ρ from the size-dependence of the $2k_F$ peak. Especially the peak in $N(k)$ is much weaker than that in $S(k)$. We expect the coefficient C of the size-dependence $N_a^{-K_\rho}$ is very small for $N(k)$.

The global features of the correlation functions for small values of J resemble the results in the large- U Hubbard model.¹²⁾ As J increases they lose this behavior and near the supersymmetric case ($J/t = 2$), the system behaves similarly to the non-interacting case. This again corresponds to the fact that the exponent K_ρ becomes 1 (free-electron value) near $J/t = 2$ ($J/t \sim 2.3$ for $n = 0.5$).¹¹⁾ $N(k)$ and $S(k)$ become almost flat in the region $k > 2k_F$, which is the same behavior as in the non-interacting case. However, note that this global features of correlation functions are non-trivial even if $K_\rho = 1$, since this exponent only guarantees that the long-range behavior of correlation functions is the same as in the non-interacting case. Actually the absolute value in the flat region is quite different from the non-interacting value. For the case of 8 electrons in 16 sites, we get

$$\begin{aligned} N(k > 2k_F) &= 0.312 \sim 0.319, \\ S(k > 2k_F) &= 0.698, \end{aligned} \tag{2.4}$$

while in the non-interacting case, $N(k > 2k_F) = S(k > 2k_F) = n = 0.5$. The sum of these two values is, however,

$$N(k > 2k_F) + S(k > 2k_F) = 1.001 \sim 1.009, \tag{2.5}$$

and this is surprisingly close to the non-interacting value ($2n = 1$). We will discuss this result in the light of the GWF in the following chapter.

Next we estimate the ground-state energy. The ground state is always singlet and non-degenerate, if we choose periodic (antiperiodic) boundary conditions for $N/2 =$ odd (even), respectively.^{12,11)} Under these boundary conditions, the energy converges smoothly to the thermodynamic limit. For $n = 0.5$ we calculate the ground-state energies in 4, 8, 12, and 16 sites clusters and fit the results to the formula

$$E/N_a = \epsilon_\infty + C_1/N_a^2 + C_2/N_a^4 + C_3/N_a^6. \tag{2.6}$$

In Fig. 2 the fitted values of ϵ_∞ are shown by a solid line. In the region $J/t \geq 3.4$ the energies cannot be fitted to this formula because the system phase separates in this region and the size-dependence is different from (2.6). To check the convergence for $J/t < 3.4$, we calculate another series of singlet energies by using a different boundary conditions, *i.e.*, antiperiodic ones for $N/2 = \text{odd}$ and vice versa.²⁷⁾ Fitting of the data to the same formula (2.6) gives another estimate of the ground-state energy, (ϵ'_∞). [In this case $C_1 > 0$, while the former fitting gives $C_1 < 0$.] The fitted values are shown in Table I. The difference between ϵ_∞ and ϵ'_∞ is very small ($\Delta\epsilon_\infty < 10^{-6}t$),²⁸⁾ which ensures the reliability of the estimate. For $n = 3/4$, we estimate similarly the ground-state energy by using 8 and 16 sites clusters with 6 and 12 electrons, respectively. The obtained ϵ_∞ is shown in Table II. Because in this case we fit the data with two parameters ϵ_∞ and C_1 , the error is larger than that in the quarter-filled case. We will use ϵ_∞ later to compare with the variational energies.

§3. Comparison with the GWF Near the Supersymmetric Case

In this section we compare the results in the previous section with the Gutzwiller wave function (GWF). The GWF is defined as

$$P_d\Phi_F = \prod_j (1 - n_{j\uparrow}n_{j\downarrow})\Phi_F, \quad (3.1)$$

where Φ_F is a simple Fermi sea. In 1D case, the analytic expression for the physical quantities were developed.^{18,19)}

First let us compare the variational energy. The expectation value of the kinetic energy is calculated as

$$E_t = \frac{\langle \mathcal{H}_t \rangle}{N_a} = -\frac{2t}{2\pi} \sum_\sigma \int_{-\pi}^{\pi} dk \cos k \langle c_{k\sigma}^\dagger c_{k\sigma} \rangle, \quad (3.2)$$

where $\langle \cdots \rangle$ indicates the expectation value in the GWF. The analytic expression for $\langle c_{k\sigma}^\dagger c_{k\sigma} \rangle$ has been given by an infinite summation.¹⁸⁾ The detailed calculation is summarized in Appendix A. Here we show that the exchange energy can be obtained in a compact form.¹⁹⁾ From the expression of $S(k)$ and $N(k)$ (see below and Appendix A), we get

$$\begin{aligned} \langle 4S_i^z S_{i+1}^z \rangle &= -\frac{1}{\pi} \{ \text{Si}(\pi) - \text{Si}((1-n)\pi) \}, \\ \langle n_i n_{i+1} \rangle &= n^2 + \frac{1}{2\pi^2} (\cos 2n\pi - 1) \\ &\quad + \frac{1}{\pi} \left(\frac{\sin n\pi}{\pi} + (1-n) \cos n\pi \right) \{ \text{Si}(\pi) - \text{Si}((1-n)\pi) \}, \end{aligned} \quad (3.3)$$

with $n = N/N_a$ being the electron density. Using a fact that the GWF is singlet,²⁹⁾ we obtain analytically

$$\begin{aligned}
E_J &= \frac{\langle \mathcal{H}_J \rangle}{N_a} \\
&= -\frac{J}{4\pi} \left\{ \left\{ 3 + \frac{\sin n\pi}{\pi} + (1-n) \cos n\pi \right\} \{ \text{Si}(\pi) - \text{Si}((1-n)\pi) \} \right. \\
&\quad \left. + \pi n^2 + \frac{1}{2\pi} (\cos 2n\pi - 1) \right\}.
\end{aligned} \tag{3.4}$$

In Fig. 3, we compare the total energy of the GWF with that of the Bethe Ansatz (BA) at $J/t = 2$. It is surprising that two results are indistinguishable for any value of n in the scale of this figure. In fact, for the half-filled or the Heisenberg case ($n = 1$), the energy of the GWF,^{16,18)}

$$E(\text{GWF})/t = -\frac{1}{2} \left[\frac{3}{\pi} \text{Si}(\pi) + 1 \right] = -1.384235 \dots, \tag{3.5}$$

is extremely close to that of the Bethe-Ansatz result,

$$E(\text{BA})/t = -2 \ln 2 = -1.386294 \dots. \tag{3.6}$$

For $n = 0.5$, analytic expressions (3.2) and (3.4) give

$$E_t/t = -0.574632 \dots, \tag{3.7}$$

$$E_J/J = -0.164230 \dots. \tag{3.8}$$

Thus the total energy of the GWF becomes

$$E(\text{GWF})/t = -0.903092 \dots, \tag{3.9}$$

which is quite close to the exact one:

$$E(\text{BA})/t = -0.903649 \dots. \tag{3.10}$$

The difference is only 0.06%, which is better than the half-filled case (0.15%).

In the low density region, we find that the coincidence is much better. We can see that the ground-state wave function for 2-electron problem at $J/t = 2$ is given by

$$|\Psi\rangle = P_d c_{k=0\uparrow}^\dagger c_{k=0\downarrow}^\dagger |0\rangle. \tag{3.11}$$

This means that the GWF is exact in the low density limit. In fact, the total energies of the GWF at $J/t = 2$ is

$$E(\text{GWF})/t = -2n + \frac{\pi^2}{12}n^3 + O(n^4), \quad (3.12)$$

which coincides with the BA results up to the order of n^3 . The detailed calculation for (3.12) is also given in Appendix A. This is consistent with the fact that the critical exponent K_ρ approaches 1 for $n \rightarrow 0$. This Fermi liquid state is nothing but the GWF.

In Fig. 4, we compare $n(k)$ for the GWF with that for the small cluster calculation. As for $n(k)$, two results almost coincide quantitatively except for the singularity at k_F . It is remarkable that the ground state of the t - J model has an enhancement of $n(k)$ in the vicinity of π , which was considered before as a pathological behavior of the GWF.¹⁷⁾ It can be shown that this enhancement originates from the correlated electron motion,

$$\langle c_{i\sigma}^\dagger c_{j\sigma} (1 - n_{i-\sigma})(1 - n_{j-\sigma}) \rangle_0, \quad (3.13)$$

where $\langle \cdots \rangle_0$ represents the expectation value in the free Fermi sea Φ_F without the Gutzwiller projection. After a straightforward calculation, (3.13) becomes

$$P_{ij\sigma}(1 - n_{-\sigma} + n_{-\sigma}^2 + \delta_{ij}n_{-\sigma} - P_{ij-\sigma}P_{ji-\sigma}), \quad (3.14)$$

and its Fourier transform is

$$n_\sigma^0(k) - 2n_{-\sigma}n_\sigma^0(k) + f_2(k). \quad (3.15)$$

Here $P_{ij\sigma}$ is the Fourier transform of $n_\sigma^0(k) = \theta(k_F - |k|)$, and f_2 is given in Appendix A as one of the lowest order terms in the analytic calculation. The enhancement of $n(k)$ in the region of $k > k_F$ is roughly reproduced from this simple lowest-order, (3.13).

The slight difference between the GWF and the exact ground state is the behavior around k_F which originates from the TL liquid nature. The GWF is essentially a Fermi liquid state with discontinuity $q = \sqrt{1 - n}$ at $k = k_F$. On the other hand, $n(k)$ in the true ground state has a power-law singularity as

$$n(k) = n(k_F) - c|k - k_F|^\alpha \text{sgn}(k - k_F) \quad (3.16)$$

with $\alpha = (K_\rho + 1/K_\rho - 2)/4$. For $n = 0.5$, K_ρ is about 0.85 and is not far from 1 of the Fermi liquid case.^{11,13)} This is the reason for the two results are relatively close to each other even in the vicinity of k_F . In order to describe these power-law behaviors around

k_F , it seems necessary to introduce low energy excited states around the Fermi surface into the trial wave function,²⁰⁾ or a long-range Jastrow factor^{21,23)} as discussed in §5.

In Fig. 5, $S(k)$ and $N(k)$ are compared with the GWF. $S(k)$ increases for $k < 2k_F$ and becomes constant for $k > 2k_F$:

$$S(k) = \begin{cases} -\ln\left(1 - \frac{|k|}{\pi}\right), & 0 \leq k < 2k_F \\ -\ln(1 - n), & 2k_F < k \leq \pi \end{cases} \quad (3.17)$$

($2k_F = n\pi$). $N(k)$ has different curves

$$N(k) = \begin{cases} \frac{1}{\pi} - \frac{|k|}{2\pi} \ln \frac{\left(1 - n + \frac{|k|}{\pi}\right)}{(1-n)}, & (0 \leq k < \min(2k_F, 2\pi - 4k_F)) \\ \frac{|k|}{\pi} - \frac{|k|}{2\pi} \ln \frac{\left(1 + n - \frac{|k|}{\pi}\right)}{(1-n)} + \ln\left(1 + n - \frac{|k|}{\pi}\right), & (2k_F < k < \min(4k_F, 2\pi - 4k_F) \\ & \text{when } 2k_F < 2\pi - 4k_F, \text{ or } n < 2/3) \\ 2 - 2n + \frac{|k|}{2\pi} \ln \frac{\left(n - 1 + \frac{|k|}{\pi}\right)}{\left(1 - n + \frac{|k|}{\pi}\right)}, & (2\pi - 4k_F < k < 2k_F \\ & \text{when } 2\pi - 4k_F < 2k_F, \text{ or } 2/3 < n < 1) \\ 2n + \ln(1 - n), & (4k_F < k < \pi \\ & \text{when } 4k_F < \pi, \text{ or } n < 1/2) \\ 2 - 2n + \frac{|k|}{2\pi} \ln \frac{\left(n - 1 + \frac{|k|}{\pi}\right)}{\left(1 + n - \frac{|k|}{\pi}\right)} + \ln\left(1 + n - \frac{|k|}{\pi}\right), & (\max(2k_F, 2\pi - 4k_F) < k < \pi \\ & \text{when } \pi < 4k_F, \text{ or } 1/2 < n < 1) \end{cases} \quad (3.18)$$

Figures 4 and 5 show that the GWF is an extremely good trial function to describe globally the 1D t - J model in the supersymmetric case, although it is not the exact ground state. The J -dependence of the variational energy for the GWF is also shown in Fig. 2 using (3.7) and (3.8). It is apparent that the GWF is very good only in the vicinity of the supersymmetric case.

It is possible to speculate the reason. An up-spin electron, for example, can hop to a neighboring site with the same magnitude $t = J/2$ independent of the state of the neighboring site (hole or down-spin electron).⁴⁾ This fact makes the up-spin part of the wave function similar to the Fermi sea where the up-spins move freely without any correlation to the down-spins. Actually the electron system without any interaction has an energy

$$E_t/t = -\frac{4}{\pi} \sin \frac{\pi n}{2} = -2n + \frac{\pi^2}{12} n^3 + O(n^5),$$

which coincides with the exact result up to $O(n^3)$.

Now we discuss the flat region of $S(k) + N(k)$ in $k > 2k_F$ which we have shown in the previous chapter (Fig. 1). The summation of them is rewritten as

$$\begin{aligned} & \frac{1}{N_a} \sum_{j,\ell} \{2\langle n_{j\uparrow} n_{\ell\uparrow} \rangle + 2\langle n_{j\downarrow} n_{\ell\downarrow} \rangle - \langle n_j \rangle \langle n_\ell \rangle\} e^{ik(r_j - r_\ell)} \\ &= \frac{4}{N_a} \sum_{j,\ell} \{\langle n_{j\uparrow} n_{\ell\uparrow} \rangle - \langle n_{j\uparrow} \rangle \langle n_{\ell\uparrow} \rangle\} e^{ik(r_j - r_\ell)}. \end{aligned} \quad (3.19)$$

Therefore it represents the density correlation between the same species of spin. The coincidence of this quantity to the non-interacting value shows that the each spin behaves freely. The Gutzwiller projection only affects the correlation between the different species of spins, such as $\langle n_{j\uparrow} n_{\ell\downarrow} \rangle$. The fact that the GWF behaves almost as a free state will be confirmed also for such quantities as charge and spin susceptibilities and magnetization curve in §6.

It seems that the fact the GWF is excellent in the supersymmetric case does not occur by chance. Recall that for the 1D supersymmetric t - J model with $1/r^2$ long-range coupling, the exact ground state is the GWF.^{30,31)} The lowest eigenvalue specified by electron density n and magnetic polarization $m = (N_\uparrow - N_\downarrow)/N_a$ consists of independent contributions of n and m ; the logarithmic correction does not exist for the critical behaviors. It is surprising that except for the long-range behaviors the main features of this long-range model are shared with the ordinary t - J model. Furthermore recently it has been found that many low-lying excited states of the above long-range t - J model, including the case of finite magnetic polarization, are represented also by Gutzwiller-projected determinantal wave functions.^{32,25,33)} Thus to elucidate the relation between these models and to study excited states by the variational approach are fascinating future problems.

§4. Fermi-Liquid-Type Jastrow Functions

In this section we study the Fermi-liquid-type wave functions to describe the t - J model away from $J/t = 2$, keeping the application to higher dimensions in mind. In many-body problems Jastrow-type wave functions with two-body correlation factors are often used. First, notice that the trial state becomes non-singlet if the Jastrow correlation is spin-dependent.³⁴⁾ Therefore we study here only the spin-independent charge density correlation:³⁵⁾

$$\Psi = \prod_{j\ell} \prod_{\sigma\sigma'} \left[1 - (1 - \eta(r_{j\ell})) n_{j\sigma} n_{\ell\sigma'} \right] \Phi_F, \quad (4.1)$$

where $r_{j\ell} = |r_j - r_\ell|$. For $\eta(r)$ simple forms are desirable, satisfying the condition of the t - J model: $\eta(0) = 0$. This condition is to project out the double occupancies. In this section we consider two cases in addition to the GWF:

$$\eta(r) = \begin{cases} \frac{2}{\pi} \arctan \frac{r}{\zeta} & \text{(a) (RJWF)} \\ 1 & \text{(b) (GWF)} \\ 1 + \frac{\alpha}{r^\beta} & \text{(c) (AJWF)} \end{cases}, \quad (4.2)$$

where $r \neq 0$ and ζ , α and β are positive variational parameters. The typical forms of $\eta(r)$ are shown in Fig. 6. In these function, $\eta(\infty) = 1$ holds and the value of $\eta(1)/\eta(\infty)$ is finite for every parameter set. This point is essentially different from the function with a long-range Jastrow factor discussed in the next section.

The form (a), which we call the repulsive Jastrow wave function (RJWF) in this paper, includes repulsive correlation. It prefers configurations with electrons mutually apart. In the limit $\zeta \rightarrow 0$, it is reduced to the GWF (b). This wave function was previously introduced to study the repulsive Hubbard model in strong correlation.²⁰⁾ In that work it was found that the RJWF lowers the variational energy in the Hubbard model and it reproduces qualitatively the enhancement at $2k_F$ of $S(k)$. Therefore we expect that the RJWF is suitable also for the small- J region of the t - J model.

An attractive Jastrow wave function (AJWF) with the correlation factor (c) favors local configurations with electrons close to each other. The parameter α adjusts the amplitude of such attractiveness; as α increases, more emphasis are laid upon attractive electron configurations. On the other hand, the other parameter β controls the decaying behavior of $\eta(r)$. With increasing β , effective attractive range becomes narrower. It is reduced to the GWF when $\alpha \rightarrow 0$ or $\beta \rightarrow 0$. We will show that the AJWF properly describes a homogeneous phase for relatively small α as well as a fully phase-separated state for large values of α .

Comparing with the RJWF and the AJWF, we may regard the GWF as a “free-electron” state in that there is no amplitude modification from the non-interacting state except for the exclusion of doubly occupied sites.

We evaluate the expectation values by the variational Monte Carlo (VMC) method.^{16,17)} This method gives virtually *exact* expectation values for given trial functions. In the VMC calculations in this work we use systems with electron number $N = 4I + 2$ (I : integer) with the periodic boundary condition. Sample numbers ($3 \times 10^4 \sim 2 \times 10^5$) and sampling intervals (50 Monte Carlo steps at the maximum) are taken so as to reduce statistical fluctuations enough. In this section we use typically 60- and 72-site systems.

Before going to the cases of $J/t \neq 2$, we check the supersymmetric case. Total energy per site of the RJWF and the AJWF for $J/t = 2$ and $n = 0.5$ are shown in Figs. 7(a) and 7(b), respectively. These figures tell us that the Jastrow correlation factors raise the variational energy and that the GWF is the best trial state for $J/t = 2$. In the following we will see that the RJWF has lower energy than the GWF for $J/t < 2$ (§4.1) and the AJWF has lower energy than the GWF for $J/t > 2$ (§4.2).

4.1 Repulsive Case

We start with a brief survey of energy. In Fig. 8, E_t/t and E_J/J in the RJWF are plotted as a function of ζ for $n = 0.5$. As ζ increases, electrons keep apart from each other and thus E_t tends to decrease and E_J increases. We show the total energy $E(\zeta)$ for $J/t = 1.0$, as an example, in Fig. 9 using the values in Fig. 8. The minimum is situated at $\zeta \sim 0.7$; the energy is considerably improved upon the GWF ($\zeta = 0$). Similarly we find that the minimum appears at $\zeta \sim 1.6$ (for $J/t = 0$), 1.2 (0.5), 0.7 (1.0), 0.4 (1.5), and 0 (2.0), respectively. The repulsive interaction represented by the magnitude of ζ becomes weaker with increasing J . Variational energies thus obtained are plotted also in Fig. 2 to compare with the exact ground-state energy.

Next, let us consider the critical value J_c below which the RJWF has a lower variational energy than the GWF. In order to estimate J_c we only have to see the ζ -dependence of the variational energy near $\zeta = 0$: if the slope of the energy at $\zeta = 0$ is positive, the optimal state is $\zeta = 0$, which is the GWF. On the other hand, if the slope at $\zeta = 0$ is negative, the variational energy has a minimum at a certain value of $\zeta > 0$ and the RJWF is more stable than the GWF ($\zeta = 0$).

In Fig. 10 variational expectation values, E_t/t and E_J/J , in the RJWF are shown for $n = 0.3$ and small ζ . From this figure we read $E_t(\zeta)/t = -0.471 - 0.0413\zeta$ and $E_J(\zeta)/J = -0.0540 + 0.0217\zeta$. Since the total variational energy is given by

$$E(\zeta) = E_t(\zeta) + E_J(\zeta), \quad (4.3)$$

the slope of $E(\zeta)$ near $\zeta = 0$ is $-0.0413t + 0.0217J$. This means that for $J/t < 0.0413/0.0217 \simeq 1.9$, the slope is negative and the RJWF improves the variational energy upon the GWF. In a similar way, we obtain the value of J_c/t also for $n = 0.5$,

0.75 and 0.833... As n increases, the statistical fluctuation becomes severe and it is not easy to estimate accurate values. However, we find $J_c/t = 2.0 \pm 0.2$ for the above densities. From this we conclude that a repulsive correlation is necessary to reproduce the ground state for $J/t < 2$. Actually the value of J_c/t ought to be slightly shifted to a larger value of J/t in the high density region, as will be seen in the next section. This is consistent with the diagonalization study.¹¹⁾

Leaving the discussion of correlation functions in the next section, here we focus on the discontinuity q of momentum distribution $n(k)$ at k_F , which is one of the characteristic properties of a Fermi-liquid-type wave function. This quantity is equal to the wave function renormalization factor and related to the inverse of the effective mass m^*/m in the Fermi liquid theory. Similarly it is the energy reduction factor in the Gutzwiller approximation. In Fig. 11 the value of q is plotted as a function of n calculated with the optimized wave function for each value of J/t .

For the supersymmetric case the result of the GWF,¹⁸⁾ $q = \sqrt{1-n}$, is shown. In this case q becomes 1 in the limit of $n \rightarrow 0$, which is the value of the non-interacting system. In the other limit $n \rightarrow 1$, q vanishes. This implies the Fermi surface vanishes, namely effective mass diverges, corresponding to the metal-insulator transition. As J/t decreases, q becomes small; the correlation affects the whole electron density in this case. Although the result for $J/t = 2.5$ includes relatively large statistical error, it is obvious that q tends to decrease, with increasing J/t from $J/t = 2.0$. Thus we conclude that the supersymmetric case is the most weakly interacting; as J/t goes away from it, the correlation effect becomes severer.

4.2 Attractive Case

We study the AJWF in this subsection. For $J/t > 2$, it is natural to expect that the attractive correlation between electrons is dominant. In Fig. 12 we show the variational expectation values of $\mathcal{H}_t$ and $\mathcal{H}_J$ for the AJWF ($n = 0.75$). E_J becomes lower and E_t becomes higher as α increases, because the amplitude of configurations with electrons located next to one another increases. Note that E_t abruptly approaches to zero and E_J to the energy of the spin system in the region $\alpha > 10$ for $\beta = 0.625 \sim 1$. This is nothing but a sign of the phase transition. We will come back to this point shortly.

First we estimate the critical values above which the GWF becomes unstable against the AJWF by studying the small- α (and various β) behavior, as in the RJWF case. We obtain $J_c/t = 2.0 \pm 0.1$ for $n = 0.5$ and 2.0 ± 0.4 for $n = 0.25$ and 0.75.

Searching the energy minimum in the α - β plane, we obtain the optimized energy for $J/t > 2$. The cases of $n = 0.5$ are included in Fig. 2. For $n = 0.75$ and $J/t = 3.3$, 3.4 and 3.5, the total energies as a function of variational parameters are shown in Figs.

13(a)-(c), respectively. The energy is improved on that of the GWF in every case. The value of α giving the energy minimum becomes large with increase of J/t ; this means the enhancement of the attractive correlation.

One can read that the aspects of the minima are quite different among three figures of Figs. 13(a)-(c). For simplicity, let us consider the case of $\beta = 1$ (empty circle). In each figure the energy curve of $\beta = 1$ has two local minima, that is, one around $\alpha = 1 \sim 2$ (minimum H) and one around $\alpha = 15$ (minimum S). In Fig. 13(a) the lowest energy is given by the minimum H, and the minimum S has a higher value. In Fig. 13(b) the two minima have comparable values. On the other hand, for $J/t = 3.5$ (Fig. 13(c)) the situation is opposite to Fig. 13(a). Thus we find a switching from the state of the minimum H to one of the minimum S around $J/t = 3.4$.

Let us see that the optimal state for $J/t > 3.4$ represents the phase separation. First, the snapshots of electron configurations taken along a Monte Carlo (MC) sweep (Fig. 14) show a formation of an electron cluster. Although small density fluctuation can be seen near the boundary, this edge effect will be irrelevant as $N_a \rightarrow \infty$. Second, the minimized energy for $J/t > 3.4$ is quite close to the energy of the Heisenberg chain corrected by electron density (Fig. 2).

To see this more quantitatively, charge-density correlation function in real space,

$$N_r = \frac{1}{N_a} \sum_i [\langle n_i n_{i+r} \rangle - n^2], \quad (4.4)$$

is plotted in Fig. 15 for $\beta = 0.75$. For $\alpha = 0$ (GWF), N_r has a negative dip in a short distance due to the exchange hole of the original Fermi sea, and falls off as r^{-2} in a long distance and converges to zero. When α is switched on, the effect of the exchange hole is compensated by the weak attractive correlation; on the other hand, long range part of N_r hardly changes. As the value of α increases further, N_r abruptly changes its behavior at $\alpha = 10$. It approaches the value of the completely separated phase ($\alpha = \infty$) expressed as

$$N_r = \begin{cases} n - n^2 - r/N_a & (0 \leq r/N_a \leq 1 - n) \\ 2n - n^2 - 1 & (1 - n \leq r/N_a \leq 1/2) \end{cases} \quad \text{for } \frac{1}{2} \leq n \leq 1 \quad (4.5a)$$

$$N_r = \begin{cases} n - n^2 - r/N_a & (0 \leq r/N_a \leq n) \\ -n^2 & (n \leq r/N_a \leq 1/2) \end{cases} \quad \text{for } 0 \leq n \leq \frac{1}{2}. \quad (4.5b)$$

In Fig. 16 N_1 , $N_{r=N_a/2}$ and $\delta_{N_a/4} \equiv -N_a(dN_r/dr)$ for $r = N_a/4$ are plotted versus α . The transition at $\alpha \sim 10$ can be seen. When a large cluster of electrons is formed, N_1 and $N_{r=N_a/2}$ are most influenced by the density fluctuation near the boundary. Inversely δ_r

for $r \sim N_a/4$ depends mainly on the fluctuation in the middle of the electron cluster, so that it represents the phase transition sharply.

In Fig. 17 $S(k)$ is shown for some values of α . For $\alpha = 0$ it has a cusp at $k = 2k_F = \pi/2$. As α becomes large $S(\pi)$ is enhanced, showing antiferromagnetic correlation for the Heisenberg chain. For $\alpha = 30$, $S(k)$ of the AJWF is considerably similar to the Heisenberg spin system corrected with n . The behavior of $S(k)$ is also consistent with the phase separation.

In this way we find the phase boundary to the phase separation is at $J/t = 3.4$ for $n = 0.75$. Similarly we obtain $J/t \simeq 3.2$ ($n = 0.25$) and $J/t \simeq 3.3$ ($n = 0.5$). These values are in good agreement with the exact-diagonalization result.¹¹⁾

§5. Tomonaga-Luttinger-Liquid-Type Jastrow Function

In this section we study the trial state proposed by Hellberg and Mele.²³⁾ For the variational states treated in the previous section, the correlation exponent is always the same as the Fermi liquid ($K_\rho = 1$). This is because the Jastrow factor $\eta(r)$ used in (4.2) approaches 1 rapidly, namely is short ranged. If the correlation factor $\eta(r)$ is long-ranged, the correlation exponent becomes non-trivial which is consistent with the TL liquid behavior. Hellberg and Mele²³⁾ showed that a variational state

$$|F(r_{i\uparrow}, r_{j\downarrow})|^\nu \Phi_F, \quad (5.1)$$

gives non-trivial exponents, where $|F(r_{i\uparrow}, r_{j\downarrow})|$ is a Slater determinant of all the electron positions. Actually the correlation exponent is related to the variational parameter ν as³⁶⁾

$$K_\rho = \frac{1}{2\nu + 1}, \quad (5.2)$$

which was derived using the asymptotic Bethe Ansatz and the scaling relations of the TL-liquid theory.

If we rewrite this wave function in the form (4.1) using the Vandermonde's determinant identity, the corresponding Jastrow correlation can be written as

$$\eta(r) = \left[\frac{N_a}{\pi} \sin\left(\frac{\pi}{N_a} r\right) \right]^\nu. \quad (5.3)$$

When $\nu > 0$, this correlation is repulsive and is attractive for $\nu < 0$. As we can see from (5.3), the factor $\eta(r)$ behaves as N_a^ν at the longest distance, $r = N_a/2$. It depends on the system size N_a , and thus it is a very long-ranged Jastrow factor which is different from the conventional Jastrow factor, (4.2). This long-range behavior stands for the effect

of phase shift of two-particle collisions and eventually changes the correlation exponent from the non-interacting value.

In Fig. 18, we show the phase diagram obtained using this trial state. The solid lines represent the contours of constant correlation exponent K_ρ . Comparing this phase diagram with that obtained from the exact diagonalization of small clusters,¹¹⁾ we find that the variational wave function is very good in the vicinity of $J/t = 2$ including the correlation exponents. However agreement is not so good near $J/t \sim 0$. For example, the optimized variational parameter ν for $J/t = 0$ is $\nu = 1$, ($\nu = 0.75, \nu = 0.5$) near $n = 0$, ($n = \frac{1}{2}, n = 1$), respectively, while the exact exponent is $K_\rho = \frac{1}{2}$, which corresponds to $\nu = \frac{1}{2}$, regardless of n . One can see this deviation directly by examining the correlation functions. Since the density correlation function $N(k)$ is exactly the same as that of the free spinless fermions at $J/t = 0$, there must not be a peak at $2k_F$. However $N(k)$ calculated with η of (5.1) has a small peak at $2k_F$ owing to the deviation of the exponent (Fig. 19(a)).

To understand the reason of this deviation, we rewrite the variational state (5.1) as³⁷⁾

$$\begin{aligned} |F(r_{i\uparrow}, r_{j\downarrow})|^\nu \Phi_F &= \prod_{i < j} |z_i - z_j|^\nu \prod_{i < j} |z_{i\uparrow} - z_{j\uparrow}| \prod_{i < j} |z_{i\downarrow} - z_{j\downarrow}| \\ &= \prod_{i < j} |z_i - z_j|^{1+\nu} / \prod_{i,j} |z_{i\uparrow} - z_{j\downarrow}|, \end{aligned} \quad (5.4)$$

apart from the sign. Here $z_{j\sigma} = \exp(2\pi i r_{j\sigma}/N_a)$ and $\{z_j\}$ represents all the electrons irrespective of their spins. On the other hand, the exact density correlation function at $J/t = 0$ is reproduced by the free spinless fermion, $\prod_{i < j} |z_i - z_j|$. We can see that it is difficult to reproduce the exact density correlation using the form (5.4).

In this connection, for the region of $J/t \sim 0$, a better trial function will be obtained as the form, $\Psi = \chi \Phi_{\text{SF}}$ on the analogy of the exact eigenfunction in the small- J/t limit,¹²⁾ where Φ_{SF} is the wave function of spinless fermion and χ is that for spin degree of freedom.³⁸⁾

Next we make a comparison of correlation functions. Figure 19(a) shows $n(k)$, $S(k)$ and $N(k)$ for the optimized wave function (5.1) at $J/t = 0$ and $n = 0.5$, together with the result of exact diagonalization. The reproducibility of the global features is not so good. In the same figure we compare the correlation functions calculated in the optimized RJWF; the two variational states give almost identical results. Actually we find the two optimized forms of $\eta(r)$ of two variational states are similar in short distance. This suggests that the global features of the correlation functions are determined mainly by the short-range behavior of the Jastrow factor.

Figures 19(b) and 19(c) show similar comparisons between the variational states and the exact diagonalization at $J/t = 1$ and 2.6, respectively. Since the values of J/t is nearer to 2, three results are close to each other except for the vicinity of k_F in $n(k)$.

Before closing this section we confirm that the long-range part of the correlation factor controls the critical behavior of correlation functions, while the short-range part determines the global features of correlation functions as well as energy. Let us consider the wave functions with four different types of correlation factors, two of which connect the correlation factors of two kind of variational states. Namely,

$$\begin{aligned}
\text{case 1)} \quad & \eta(r) = \eta_{\text{TLL}}(r) && \text{for all } r, \\
\text{case 2)} \quad & \eta(r) = \begin{cases} \eta_{\text{FL}}(r), & \text{for } r < r_c; \\ \eta_{\text{TLL}}(r), & \text{for } r \geq r_c, \end{cases} \\
\text{case 3)} \quad & \eta(r) = \begin{cases} \eta_{\text{TLL}}(r), & \text{for } r < r_c; \\ \eta_{\text{FL}}(r), & \text{for } r \geq r_c, \end{cases} \\
\text{case 4)} \quad & \eta(r) = \eta_{\text{FL}}(r) && \text{for all } r,
\end{aligned}$$

where η_{TLL} denotes $\eta(r)$ of (5.3), η_{FL} either that of the RJWF or of the AJWF (4.2), and r_c is a certain value of r which divides $\eta(r)$ into a short-range part and a long-range part. We choose the variational parameters and r_c so that the two parts may be smoothly connected. By using these correlation factors, we perform VMC calculations for the energy, $n(k)$, $S(k)$ and $N(k)$. We fix the system size to $N_a = 100$ for $n = 0.5$ and take 5×10^4 samples for each case.

For the repulsive case we choose $r_c = 5$, $\nu = 0.5$ (the optimal value for $J/t \sim 0.7$) and $\zeta = 6.9847$. In Table III(a) we show expectation values of several physical quantities for the four cases. $\delta n(k)$ in the last two columns indicates the differences of $n(k)$ between the two possible k -points adjacent to k_F from inside and outside, respectively. For the bulk quantities like E_t/t , E_J/J and $n(k=0)$, the cases 1) and 3) give similar values, which are different from the cases 2) and 4). This implies that the short-range part of the correlation factor is responsible for the bulk properties like energy and the magnitude of correlation functions. On the other hand, for $\delta n(k)$ the cases 1) and 2) have similar values compared with the cases 3) and 4). This indicates the long-range part controls the critical behavior of correlation functions.

In Table III(b), the result of the same quantities in the attractive regime is summarized. Here we select $r_c = 10$ and $\nu = -0.15$ (the optimal value for $J/t \sim 2.5$), and the two parameters are determined by requesting $\eta_{\text{TLL}}(1) = \eta_{\text{AJ}}(1)$ and $\eta_{\text{TLL}}(r_c) = \eta_{\text{AJ}}(r_c)$ as $\alpha = 0.6804$ and $\beta = 0.5481$. The tendency agrees with the repulsive case. These facts explain the similarity of $n(k)$ and the slight energy difference shown in Figs.19.

§6. Static Properties of Charge and Spin

In this section we focus on the behavior of charge susceptibility χ_c and spin susceptibility χ_s . Since the trial states in the half filling are always Mott-insulating for the t - J model, we can see the critical behavior variationally, and discuss the difference between the present case and the Brinkman-Rice transition (Appendix B).

We calculate χ_c and χ_s from the VMC data for systems with finite sizes from the formulae:

$$\chi_c^{-1} = \frac{\partial^2 E}{\partial n^2} = \frac{N_a^2}{4} \{E(N+2, 0) + E(N-2, 0) - 2E(N, 0)\}, \quad (6.1)$$

and

$$\chi_s^{-1} = \frac{\partial^2 E}{\partial m^2} = \frac{N_a^2}{16} \{E(N, 8) + E(N, 0) - 2E(N, 4)\}, \quad (6.2)$$

where $E(N, M)$ is total energy per site of N -electron systems with $M = N_\uparrow - N_\downarrow$. Henceforth we take $1/t$ as the unit of χ_c and χ_s . We confirm that the size dependence is mostly negligible for the systems we use: $N_a = 100 \sim 200$. In contrast to the Hubbard model in the strong coupling regime, relatively accurate estimate of χ is possible for the 1D t - J model because of the less statistical fluctuations. In this section, we mainly use the wave function (5.3) and GWF. Typically $5 \times 10^4 \sim 2 \times 10^5$ independent VMC samples are used for each value of the parameter ν . To search the optimized value of $E(N, M)$ for each N and M , we pick out 61~121 values of ν between -1 and 2 .

6.1 Charge Susceptibility

In Fig. 20 χ_c is shown for several values of J/t . Here we observe that with increasing J/t , χ_c becomes large. This is because enhanced attractive interaction between electrons enlarges charge compressibility $\kappa (= \chi_c/n^2)$. In the high electron density region ($n \sim 1$) χ_c for every value of J/t is divergent as $n \rightarrow 1$. This divergence is due to the strong correlation effect, which suppresses charge fluctuation; this is in contrast with the non-interacting case, where $\chi_c^{-1} = \pi \sin(n\pi/2)$ and remains a finite value $1/\pi$ as n approaches 1. For $J/t = 0$ and 2 the exact values are known; the spinless fermion result $\chi_c^{-1} = 2\pi \sin(n\pi)$ for the former case, and the Bethe Ansatz solution for the latter.^{4,9)} In both cases the exact χ_c diverges as $\chi_c \propto 1/\delta$ ($\delta = 1 - n$) in the limit of $n \rightarrow 1$. The variational result is quantitatively similar to the exact one. To see this divergence more closely, we plot chemical potential $\mu = \partial E / \partial n$ vs. δ^2 for $J/t = 0$ and 2 in Fig. 21. For $J/t \leq 2$ we can fit μ as $\mu = \mu_0 - a\delta^2$ in the vicinity of the half filling, although the linearity is not so clear for $J/t > 2$. Since $\chi_c = \partial n / \partial \mu$, the coefficient a is related to the divergence of χ_c as $\chi_c = 2a/\delta(\delta \rightarrow 0)$. From Fig.21, we determine this coefficient $2a$ for a couple of values of J/t , which are shown in Table IV.

As can be seen in Table IV, the estimation by the variational state is in good agreement with the exact value at $J/t = 0$. However at $J/t = 2$, the deviation is quite large. This is probably because the range of linear behavior of μ vs. δ^2 is rapidly reduced as J/t increases.⁹⁾

The divergence of χ_c near the Mott transition has been understood from the Bethe Ansatz. Using the correlation exponent K_ρ and the charge velocity v_c , χ_c can be written as⁵⁻⁸⁾

$$\chi_c = \frac{2}{\pi} \frac{K_\rho}{v_c}.$$

Since v_c vanishes linearly as $\delta \rightarrow 0$, $v_c = b\delta$, χ_c diverges as^{39,10,14)}

$$\frac{2}{\pi} \frac{K_\rho}{b} \frac{1}{\delta}.$$

Since $K_\rho \rightarrow 1/2$ as $\delta \rightarrow 0$ ¹¹⁾ the coefficient $2a$ is solely related to the coefficient b , which is $2\pi \geq b \geq 3\pi\zeta(3)/(16(\ln 2)^2)$ for $0 \leq J/t \leq 2$.^{11,9)} However, for $J/t > 2$, we cannot expand μ as $\mu = \mu_0 - a\delta^2$, but fit μ as $\mu = \mu_0 - a\delta^p$ instead. The leading power p is estimated as $1 < p < 2$, namely $p = 1.8$ (for $J/t = 2.0$), 1.5 (2.5) and 1.3 (3.0). Although χ_c diverges as $\delta \rightarrow 0$ for $J/t \geq 2$, we have not understood the origin of this power. This may be due to the poorness of the trial wave function of (5.1) or due to an anomalous dependence of v_c as $v_c \sim a\delta^{p-1}$. At any rate, we can consider that this divergence is attributed to the divergence of density of state at the band edge of the spinless fermion.

In low electron density area ($n \sim 0$) χ_c again diverges except for the case of $J/t = 2.5$, in which the variational state becomes unstable against phase separation and χ_c becomes negative. One can find that the divergence of χ_c is proportional to $1/n$ by plotting μ as a function of n^2 . The coefficients of $1/n$ are shown also in Table IV. Since for $J/t = 2$ the trial wave function (GWF) is exact in the limit $n \rightarrow 0$, the exact value is within the range of error. Furthermore, the GWF result and the exact one are extremely close to the non-interacting gas, which means a “free electron” state is realized in the supersymmetric case. Actually using the variational energy (3.12), we obtain

$$\chi_c = \frac{2}{\pi^2 n} + O(n^0),$$

which is the same as in the non-interacting case. As n increases, however, the suppression of charge fluctuation in the t - J model prevents the wave function from the free-electron behavior.

For $J/t = 0$ the variational value is a little different from the exact one. This difference corresponds to the deviation of K_ρ in this area, as described in the previous

section. The divergence of χ_c is not due to the correlation effect, but simply to the divergence of the density of state at the band edge.

6.2 Magnetic Properties

First, we discuss spin susceptibility under zero field. Figure 22 shows χ_s for a couple of values of J/t . In sharp contrast to χ_c , χ_s does not diverge as $n \rightarrow 1$ for every value of J/t but remains a finite value close to that of the Heisenberg chain.⁴⁰⁾ The divergence of χ_c hardly affects χ_s ; this is due to the separation between spin and charge degrees of freedom in the low-energy excitations.

For $J/t = 0$, all the spin configurations are degenerate, hence χ_s is infinite. This aspect is special in 1D. By introducing J/t , this degeneracy is lifted and the value of χ_s becomes finite except for the low density limit, which is shown in Fig. 22. In the TL liquid theory, χ_s can be represented as^{5,6,39,7)}

$$\chi_s = \frac{2}{\pi} \frac{1}{v_s}$$

where v_s is the spin velocity. Basically v_s is proportional to the exchange coupling J and thus χ_s decreases as J/t increases, which means that the enhanced exchange coupling hinders the response of spins to the magnetic field. For a low density area ($n \sim 0$) χ_s diverges since $v_s \propto n$, which is due to the divergence of density of states. On the other hand as $n \rightarrow 1$, χ_s approaches that of Heisenberg chain,

$$\chi_s \rightarrow \frac{2}{\pi} \frac{1}{v_{sw}}$$

with v_{sw} being the spin wave velocity of Heisenberg chain: $v_{sw} = J\pi/2$.

For the supersymmetric case, we observe that the variational results agree quite well with that of the non-interacting system (Pauli paramagnetism) $\chi_s^{-1} = \pi \sin(n\pi/2)$, especially in low density region. Here the idea of the GWF as a “free electron” state is again useful. Like χ_c , however, the two results become a little apart as $n \rightarrow 1$. For $J/t = 2.5$ and $n < 0.1$, the decrease of χ_s is due to the phase separation.

Now let us turn to the case under a finite magnetic field $g\mu_B H$, and here we put $g = 2$ and $\mu_B = 1$. Applying an external field along z -axis, a Zeeman term,

$$\mathcal{H}_{\text{ext}} = -2H \sum_j S_j^z = -N_a H m, \quad (6.3)$$

is added to the original Hamiltonian (2.1). Total energy per site is written as,

$$E = E(m, n) - H m, \quad (6.4)$$

where $E(m, n)$ is total energy per site with electron density n and magnetization m under zero field.

In Fig. 23 $E(m, n)$ is shown for $n = 0.5$ and 1.0 as a function of m ($0 \leq m \leq n$). For each case the energy is a monotonically increasing function of m . By minimizing the total energy (6.4), we obtain the magnetization curves, which are shown in Fig. 24. The critical field H_s at which spin saturates is determined from the slope of $E(m, n)$ near $m = n$. The value of H_s is $0.34(J/t = 1.0)$, $0.99(2.0)$ and $1.32(2.5)$ for the quarter filling, and $2.000(2.0)$ for the half filling.

For the half filling, the data of the GWF is very close to the exact value (Heisenberg antiferromagnet)⁴⁰⁾ for all the range of H .⁴¹⁾ In the weak field limit, m/H is nothing but χ_s , the similarity of the two results is obvious from Fig. 22.

For the quarter filling, m saturates at smaller H as J/t decreases. This is naturally understood since the energy to excite the system to higher spin state becomes less as J/t decreases. In the supersymmetric case, the GWF is in good agreement with the BA result also for the quarter filling.⁴²⁾ Furthermore, the non-interacting result agrees well for all the values of H/t .

6.3 Comparisons and Discussions

First, we compare the above result with the Hubbard model. Exact results^{43,44,39)} show that in the limit of $n \rightarrow 1$, χ_c diverges as $\chi_c = \alpha/\delta$, where α is a numeral factor which depends on U/t .³⁹⁾ The value of α changes from zero for $U/t = 0$ to $1/2\pi^2$ for $U/t = \infty$, which is the same with the t - J model with $J/t = 0$. On the other hand, χ_s converges upon a finite value as n approaches 1.⁴³⁾ In the strong- U limit the expansion coefficient in t^2/U of χ_s is the same as the t - J model. These features qualitatively agree with the variational results of the present study as well as the exact one for the t - J model.

Meanwhile, Otsuka⁴⁵⁾ and Furukawa and Imada¹⁰⁾ investigated the critical behavior of χ_c and χ_s for the Hubbard model on 2D square lattice by using quantum Monte Carlo methods. According to their results, essentially the same properties with the 1D models are observed. Thus one can consider that a universal profile of a kind of Mott transition appears in these results of χ_c and χ_s .

Keeping these in mind, next let us compare with the Brinkman-Rice transition in the Hubbard model. As summarized in Appendix B, χ_s calculated with Gutzwiller approximation diverges when $U \rightarrow U_c$ ($n = 1$) or $n \rightarrow 1$ ($U \geq U_c$). On the other hand, χ_c remains finite for a finite value of U , even if $U > U_c$, although effective mass m^*/m diverges similarly as χ_s . This indicates that the Brinkman-Rice transition describes a quite different type of metal-insulator transition from those in the 1D and 2D Hubbard models and the 1D t - J model.

Lastly we mention the results in the long-range t - J model.³⁰⁾ In this model, susceptibilities are written as

$$\chi_c^{-1} = \frac{\pi^2}{2}(1 - n), \quad \chi_s^{-1} = \frac{\pi^2}{2}(1 - m). \quad (6.6)$$

Notice that χ_s does not depend on n and χ_c does not on m , since the contributions to energy of n and m are mutually independent, and that there are no system size dependence, because the size-dependent terms in energy are exhausted in the linear order. The value of χ_s is constant ($2/\pi^2$) under zero field irrespective of n , which is the same for the nearest-neighbor Heisenberg model and is close to the variational value (GWF). The divergent behavior of χ_c near the half filling is also similar to the t - J model (see Table IV). On the other hand, a quite different feature appear in the low electron density region, where there is no divergence. This difference is originated in the band structure of the model; the non-interacting long-range model has linear energy dispersion and there is no divergence in density of state at the band edge. From this we can see that electron correlation affects severely high-electron-density regime, while in the low-density regime the density of states of the original non-interacting system determines the charge susceptibility.

In Fig. 24 we also plot the magnetization curve of the long-range t - J model:^{46,32)}

$$m = 1 - 2\sqrt{\frac{1}{4} - \frac{H}{\pi^2 t}}. \quad (6.7)$$

This formula does not depend on n . The critical field H_s for the long-range model is somewhat larger ($\pi^2/4$ for $n = 1$ and $3\pi^2/16$ for $n = 0.5$) than the value of the ordinary t - J model. And the difference is larger for $n = 0.5$. This is probably because the long-range exchange terms tend to disturb ferromagnetic spin alignment. Especially in the low density region, where the particle distance is large, the long-range terms play important roles.

§7. Summary and Discussion

We have pursued the ground-state properties of the one-dimensional t - J model in the light of wave functions. By comparing the variational Monte Carlo results with those of the exact diagonalization, the Bethe Ansatz and the Gutzwiller approximation, we have obtained some remarkable aspects as follows:

- [1] From diagonalization, exact energy, momentum distribution, and spin and charge correlation functions are obtained, which show unusual behaviors as J/t increases.
- [2] In the supersymmetric case ($J/t = 2$) the Gutzwiller wave function is an extremely good state for bulk quantities. In the low-density limit the GWF becomes exact.
- [3] Whole parameter space spanned by electron density n and coupling strength J/t is well described by the repulsive or the attractive Jastrow-type wave functions. The parameter space can be roughly divided into:

- (a) $J/t < 2$ repulsive region (RJWF),
- (b) $J/t = 2$ free-like region (GWF),
- (c) $J/t > 2$ attractive region (AJWF).

In the region (a), the electron hopping term is dominant. In the region (c), dominant is the exchange term, which induces attractive interaction. In the supersymmetric case (b), the two terms are well balanced and a kind of “non-interacting” state is realized, especially for the low electron density.

- [4] Phase transition from a homogeneous state to a phase-separated state is quantitatively described within the AJWF.

- [5] In the Jastrow wave functions, a short-range part of intersite correlation factors are responsible for relatively high energy processes which determine bulk properties like energy and magnitude of correlation functions. On the other hand, a long-range part is mainly concerned in low energy processes near the Fermi surface, which cause the critical properties characteristic of the Tomonaga-Luttinger liquid.

- [6] The Jastrow wave functions reproduces charge and spin susceptibilities and magnetization curve correctly, in contrast with the Gutzwiller approximation.

Keeping these results in mind, we mention some remaining issues.

In the region of low electron density and $J/t > 2$, there exists a spin gap state (without a charge gap).^{11,47)} We have not found an indication of a spin gap in the trial functions used. On the other hand, Chen and Lee⁴⁸⁾ introduced a trial state for a gas of singlet pairs, and showed that there is a region where this function is stabler than the TL-liquid wave function (5.1).

An interesting extension of the present method is to 2D systems. In 2D we do not know even the ground state—the Fermi liquid or the TL liquid for the metallic regime.

Furthermore, magnetically ordered phases can be stabilized, near the half filling.⁴⁹⁾ Actually the TL-liquid wave function has been extended to a 2D system by Valenti and Gros.⁵⁰⁾ According to their results, the energy lowering by their function is very small (1%) compared with the simple Gutzwiller wave function. Also the critical exponent at k_F in the momentum distribution is small, assuming that it exists. Since critical properties are in a low energy scale, it may not be easy to judge the realization of a TL-liquid state in 2D only by the stability in energy.

Recently the behaviors of specific-heat coefficient, effective mass, χ_c , χ_s , etc. are investigated experimentally for the high- T_c superconductors and related Mott insulators,⁵¹⁾ in connection with the metal-insulator transition. The results of these experiments together with the theoretical calculations^{45,10)} have suggested reconsideration of the appropriate Hamiltonian, namely whether the simple t - J model is pertinent to describe various aspects of the high- T_c cuprates.

In these contexts, 2D systems have to be further studied with the variation theory.

Acknowledgment

The authors are grateful to T.M. Rice, H. Shiba, Y. Kuramoto, D. Vollhardt, W.O. Putikka, M.U. Luchini, S. Sorella and P.-A. Bares for fruitful discussions. One of the authors (H.Y.) thanks N. Kawakami, W. Metzner, Y. Ōno, T. Pruschke, K. Sano, B.S. Shastry, P.G.J. van Dongen and F.C. Zhang for useful comments. This work is supported partly by Grant-in-Aids for Scientific Research on Priority Areas, “Computational Physics as a New Frontier in Condensed Matter Research” and “Science of High- T_c Superconductivity” and for Encouragement of Young Scientists given by Ministry of Education, Science and Culture, Japan.

Appendix A: Analytical Approach to the Gutzwiller Wave Function.

In this appendix, we summarize the analytic expressions for various expectation values in the GWF. They were developed by Metzner and Vollhardt,¹⁸⁾ and by Gebhard and Vollhardt¹⁹⁾ for the Hubbard model. In order to apply to the 1D t - J model, we carry out the calculation of $\langle n_i n_j \rangle$ and $\langle S_i^z S_j^z \rangle$.

The momentum distribution for spin σ is obtained by an infinite summation¹⁸⁾

$$n_\sigma(k) = n_\sigma^0(k) - (1-g)^2 n_{-\sigma} n_\sigma^0(k) + \frac{1}{(1+g)^2} \sum_{m=2}^{\infty} (g^2 - 1)^m \{1 - (1-g^2) n_\sigma^0(k)\} f_{m\sigma}(k), \quad (\text{A.1})$$

where g is identical to $\eta(0)$ in our notation (eq. (4.1)), and thus $g = 0$ for the t - J model. $n_\sigma^0(k)$ is the momentum distribution of the non-interacting system given by $n_\sigma^0(k) = \theta(k_F - |k|)$, and $n_\sigma = n/2$. In 1D case, $f_m(k)$ is given by a polynomial of order $\leq m$. According to the notation in Ref.¹⁸⁾, we can summarize as follows:

$$f_m(k) = \begin{cases} n^m R_m(k), & \text{(in region (I) : } 0 \leq k \leq k_F) \\ n^m Q_m(k) + C_{m-1}, & \text{(in region (II) : } k_F \leq k \leq \min(3k_F, 2\pi - 3k_F) \\ C_{m-1}, & \text{(in region (III) : } 3k_F \leq k \leq \pi, \text{ when } 3k_F < \pi) \\ n^m (Q_m(k) + Q_m(2\pi - k)) + C_{m-1}, & \text{(in region (IV) : } 2\pi - 3k_F \leq k \leq \pi, \text{ when } 2\pi - 3k_F < \pi) \end{cases} \quad (\text{A.2})$$

where

$$\begin{aligned} C_{m-1} &= (-1)^m \frac{n^m}{2m}, \\ R_m(k) &= \sum_{j=1}^m \frac{R_m^{(j)}}{j!} \left(\frac{k}{2\pi n} - \frac{1}{4} \right)^j, \\ Q_m(k) &= \sum_{j=1}^m \frac{Q_m^{(j)}}{j!} \left(\frac{k}{2\pi n} - \frac{3}{4} \right)^j. \end{aligned} \quad (\text{A.3})$$

The coefficients of these Taylor series are determined via a recursion relation;

$$\begin{aligned} 2(m-j+1)R_{m+1}^{(j)} &= -(2m-2j+1)R_m^{(j)} - Q_{m+1}^{(j+1)}, \\ Q_{m+1}^{(j+2)} &= 2(m-2j)Q_{m+1}^{(j+1)} + 2mR_m^{(j)} - 4j(m-j+1)(R_m^{(j)} + R_{m+1}^{(j)}), \end{aligned}$$

$$R_{m+1}^{(m+1)} = \begin{cases} 0 & m+1 = \text{odd} \\ -2Q_{m+1}^{(m+1)}, & m+1 = \text{even} \end{cases} \quad (\text{A.4})$$

with initial values

$$R_1^{(j)} = -\frac{1}{2}\delta_{j,0},$$

$$Q_{m+1}^{(0)} = Q_{m+1}^{(1)} = 0.$$

Apparently the series in (A.1) gives an expansion with respect to n in the low density region. For $m = 2$, we get

$$f_2(k) = \begin{cases} n^2 \left(\frac{k^2}{4\pi^2 n^2} + \frac{5}{16} \right) & \text{in (I)} \\ -\frac{n^2}{2} \left(\frac{k}{2\pi n} - \frac{3}{4} \right)^2 + \frac{n^2}{4} & \text{in (II)} \\ \frac{n^2}{4} & \text{in (III)} \\ -\frac{n^2}{2} \left(\frac{k}{2\pi n} - \frac{3}{4} \right)^2 - \frac{n^2}{2} \left(\frac{2\pi-k}{2\pi n} - \frac{3}{4} \right)^2 + \frac{n^2}{4} & \text{in (IV)} \end{cases} \quad (\text{A.5})$$

Then the kinetic energy in the dilute limit is

$$E_t = -2t \left(n - \frac{n^2}{2} - \frac{\pi^2}{24} n^3 - \frac{n^3}{3} \right) + O(n^4). \quad (\text{A.6})$$

Compact analytic expressions for $S(k)$ and $N(k)$ are given in (3.17) and (3.18). Their Fourier transforms give the spin and charge correlation functions in real space. Through a straightforward calculation, we get

$$4\langle S_i^z S_{i+r}^z \rangle = \frac{(-1)^r}{\pi r} \{ \text{Si}(\pi r) - \text{Si}((1-n)\pi r) \}, \quad (\text{A.7})$$

and

$$\begin{aligned} \langle n_i n_{i+r} \rangle &= n^2 + \frac{1}{2\pi^2 r^2} (\cos 4k_F r - 1) \\ &\quad - \frac{(-1)^r}{\pi r} \left\{ \frac{\sin n\pi r}{\pi r} + (1-n) \cos n\pi r \right\} \{ \text{Si}(\pi r) - \text{Si}((1-n)\pi r) \}, \end{aligned} \quad (\text{A.8})$$

where r is an integer, $r \geq 1$. When $r = 1$, (A.7) and (A.8) give the exchange energy given in (3.3). In the low density limit, we obtain

$$\langle S_i^z S_{i+1}^z \rangle = -\frac{n^2}{8} - \frac{n^3}{12} + O(n^4),$$

and

$$\langle n_i n_{i+1} \rangle = \frac{n^2}{2} + \frac{n^3}{3} + O(n^4). \quad (\text{A.9})$$

Total energy is

$$E = -2tn + \left(t - \frac{J}{2} \right) n^2 + \frac{\pi^2}{12} t n^3 + \left(\frac{2}{3} t - \frac{1}{3} J \right) n^3 + O(n^4). \quad (\text{A.10})$$

At $J/t = 2$, we get (3.12).

Appendix B: χ_s and χ_c around Brinkman-Rice Transition.

Brinkman and Rice discussed the metal-insulator transition for the Hubbard model based on the Gutzwiller approximation (GA).⁵²⁾ Although it was confirmed by solving the variation problem accurately that this transition does not exist in the realistic (1,2 and 3) dimensions,^{17,18)} the conception of the Brinkman-Rice transition is still widely used. In this Appendix we briefly review the behavior of χ_s and χ_c in the GA, especially around the Brinkman-Rice transition for the comparison in §6.⁵³⁾

According to the GA, the state of $n \neq 1$ in the Hubbard model is always metallic and has a Fermi surface with a finite discontinuity q of $n(k)$ at $k = k_F$. On the other hand, in the half filling the GA gives a metallic state for $U < U_c$ and an insulating one for $U > U_c$, where $U_c = 8|\varepsilon_0|$ and ε_0 is the energy of the non-interacting system; the Brinkman-Rice transition occurs at $U = U_c$. When U increases from under U_c fixing $n = 1$, χ_s as well as effective mass $m^*/m(\propto q^{-1})$ diverges as $1/(1 - (U/U_c)^2)$. χ_s and m^*/m remain infinite for $U \geq U_c$. Meanwhile, χ_c decreases with increasing U and vanish at $U = U_c$ and then increases for $U > U_c$. In Fig. 25 we actually plot the numerical GA values of χ_s and χ_c . According to the Fermi liquid theory, charge susceptibility is related to m^*/m as

$$\chi_c = \frac{m^*/m}{1 + F_0^s} \chi_c^0, \quad (\text{B.1})$$

where F_0^s is the usual Landau parameter and χ_c^0 is the value for the non-interacting case. Therefore F_0^s is more divergent than m^*/m at $U = U_c$.

- 41) For the Hubbard model with finite U/t in the half-filled band, the behavior of the GWF is different. As H approaches H_s , total energy comes to have two local minima, one of which is at $m = n$. And the global minimum switches from one at $0 < m < n$ to the other at $m = n$ abruptly. Thus m has a jump to the full momentum at the critical field. This aspect is common with the Gutzwiller approximation⁵³⁾ but not consistent with the exact result.⁴³⁾

Table III Comparison of expectation values for four kinds of correlation factors hybridized (a) between the RJWF eq.(4.2) ($\zeta = 6.9847$) and eq.(5.1) ($\nu = 0.5$) for the repulsive case, and (b) between the AJWF eq.(4.2) ($\alpha = 0.6804$, $\beta = 0.5481$) and eq.(5.1) ($\nu = -0.15$) for the attractive case. Digits include some statistical errors.

Figure Captions

- Fig. 1** (a) The momentum distribution function, (b) spin correlation function, and (c) charge correlation function for the quarter-filled case at $J/t = 0.5, 1.0, 2.0$ and 3.0 obtained in the exact diagonalization of the systems with 4, 8, 12 and 16 sites. For $J = 0$, we show the result in the wave function for the $U \rightarrow \infty$ Hubbard model with 52 sites.^{12,15)}
- Fig. 2** Ground-state energy of the 1D t - J model as a function of J/t at $n = 0.5$. Extrapolated values ($N_a \rightarrow \infty$) of the exact diagonalization, the energy of the fully phase separated (Heisenberg) state, and variational energies of the three types of variational functions are compared. The transition to a phase separated state occurs at $J/t \sim 3.3$ shown by a hollow arrow. In the VMC calculations systems with 50-100 sites are used.
- Fig. 3** Comparison of the total energy per site between the Gutzwiller wave function (closed circles) and Bethe Ansatz (Solid line) for $J/t = 2$ as a function of electron density. Although the VMC results for $N_a = 102$ is plotted in the figure, the analytic expression for the Gutzwiller wave function is available as in the text. The non-interacting case is also shown.
- Fig. 4** Comparison of momentum distribution function between the GWF (solid line) and the exact diagonalization (open and closed circles) at $J/t = 2$. The analytic expressions for the GWF have been obtained in Ref.^{18,19)} and given in Appendix A. Here we show the results of VMC calculations in 60- and 72-site systems with 5×10^4 samples. For the diagonalization, the data in $N_a = 4, 8, 12$ and 16 sites for $n = 0.5$ and $N_a = 8$ and 16 sites for $n = 0.75$ are shown.
- Fig. 5** Comparison of spin and charge correlation functions between the GWF (solid line) and the exact diagonalization (open and closed circles) at $J/t = 2$. Numerical results are obtained similarly as in Fig. 4.
- Fig. 6** Correlation factor $\eta(r)$ for three types of Fermi-liquid-type wave functions. Typical values of the parameters are chosen for each case.
- Fig. 7** Variational expectation values of total energy in the supersymmetric case for (a) the RJWF and for (b) the AJWF. The value of the GWF is shown by an arrow on the vertical axis. In this calculation 3×10^4 samples are used for a 60-site system.
- Fig. 8** Expectation values of two energy component $\mathcal{H}_t$ (solid circle) and $\mathcal{H}_J$ (open circle) per site for the RJWF for $n = 0.5$. The value of the GWF ($\zeta = 0$) is shown by arrows on the vertical axis. We use 3×10^4 samples for a 60-site system.
- Fig. 9** Energy expectation values for the RJWF at $J/t = 1.0$. Arrow on the vertical axis is the value of the GWF and that of the exact diagonalization (extrapolated values

for $N_a \rightarrow \infty$).

- Fig. 10** Expectation values of two energy component $\mathcal{H}_t$ (solid circle) and $\mathcal{H}_J$ (open circle) per site for the RJWF and for small- ζ region. In this VMC calculation 10^5 samples are collected for a 72-site system.
- Fig. 11** Discontinuity of momentum distribution $n(k)$ at k_F as a function of n . The optimized Fermi-liquid-type wave function is used for each value of n and J/t . The size of the symbols represent the relative magnitude of possible error. For the cases $n \rightarrow 0$ and $J/t \rightarrow 0$ and for the AJWF it is not easy to determine the value accurately owing to the difficulty in optimizing the parameters.
- Fig. 12** Variational expectation values of (a) $\mathcal{H}_t$ and (b) $\mathcal{H}_J$ per site for the AJWF. The arrow on the left vertical axis shows the value of the GWF ($\alpha = 0$). The arrows on the right axis in (b) shows the value of the Heisenberg chain (Bethe Ansatz) multiplied by n . The sample number is 3×10^4 for each point and $N_a = 72$.
- Fig. 13** Total energy of the AJWF for a couple of values of J/t around the phase transition. The same symbol with Fig. 12 is used for each value of β . (a) corresponds the homogeneous regime, (b) is the case near the phase transition, and (c) is in the phase-separated regime. The arrow on the left vertical axis shows the value of the GWF. The Heisenberg value corrected by the electron density is given by $-n(J/t) \ln 2$: $-1.8195 \dots$ for $n = 0.75$ and $J/t = 3.5$.
- Fig. 14** Snapshots of the electron configurations in the VMC sweep for $N_a = 60$, $n = 0.5$ at $J/t = 3.4$ (separated phase). Each horizontal line represents the one-dimensional system. An solid (open) circle means an up-(down-)spin electron, and an null space (horizontal line) an empty site. In the Monte Carlo sweep, the configuration of the system evolves vertically. Before taking these snapshots, 3000 MC steps are discarded for obtaining the statistical equilibrium. Sampling interval is determined ($I = 20\text{MCS}$) so as to make the acceptance ratio per electron larger than the unit.
- Fig. 15** Real-space charge density correlation function for the AJWF are shown for various values of α . The value of β is fixed at 0.75, which gives minima approximately around the phase transition. The solid line shows the values of the completely separated phase ($\alpha = \infty$). The system size is 60 sites and 5×10^4 samples are used.
- Fig. 16** Real-space correlation function N_r for the nearest neighbor sites and its derivative δ_r for $r = N_a/2$ are plotted as a function of α . Arrows on the vertical axes of the left and right represent the values of $\alpha = 0$ (GWF) and $\alpha = \infty$ (completely separated state), respectively. The used data are the same ones in Fig. 15.
- Fig. 17** Spin correlation function for the AJWF for various values of α . The solid line represents the value of the Heisenberg chain obtained by the exact diagonalizations,

which is corrected by the electron density. The system size is 60 sites and 5×10^4 samples are used.

Fig. 18 Phase diagram of the 1D t - J model calculated in the TL-liquid wave function (5.1). The curves show the contours of constant correlation exponent K_ρ . The used system has 100 sites.

Fig. 19 Comparison of momentum distribution function $n(k)$, spin and charge correlation functions, $S(k)$ and $N(k)$ among the TL-liquid wave function (bold solid line), the Fermi-liquid-type wave function (dot) and the exact diagonalization (open diamond, open circle and exceptionally thin solid line for $N(k)$ of $J/t = 0$) for (a) $J/t = 0$ ($\nu = 0.75$ for the TL-liquid state, $\zeta = 1.6$ for the RJWF), (b) $J/t = 1$ ($\nu = 0.37$, $\zeta = 0.7$) and (c) $J/t = 2.6$ ($\nu = -0.19$ for the TL-liquid state, $\alpha = 0.4$ and $\beta = 1.0$ for the AJWF). For the variational calculations, 10^5 samples are averaged for 220-site systems. Total energy for each case is also given in digits (the last digit for each include the ambiguity due to the statistical fluctuations). For exact diagonalization, 52-site system is used in (a) and up to 16-site systems in (b) and (c).

Fig. 20 Charge susceptibility vs. n for some values of J/t . Symbols are the results of the optimized TL-liquid state. Solid line for $J/t = 0$ and 2^9) represents the exact analytic value. Dashed line is the result for the non-interacting system. Dotted line for $J/t = 1.0$ and 2.5 is a guide to the eyes. The sizes of the symbols represent the relative magnitude of possible error. 50 ~ 210-site systems are used.

Fig. 21 Chemical potential as a function of δ^2 for $J/t = 0$ and 2 . Symbols indicate different system sizes, namely $N_a = 200$ (solid diamond), 150 (open circle), 100 (solid circle), 70 (solid square), 50 (open diamond).

Fig. 22 Spin susceptibility vs. n for some values of J/t . Open circle is the result of the GWF for $J/t = 2$ and open diamond is the result of the optimized TL-liquid state. Solid line for $J/t = 2$ represent the exact analytic value.^{4,9)} Dashed line is the value for the non-interacting system. Dotted line for $J/t = 1.0$ and 2.5 is a guide to the eyes. Arrow on the right vertical axis shows the exact value for the Heisenberg antiferromagnet $2/\pi^2$ for $J/t = 2$.⁴⁰⁾ The sizes of the symbols represent the relative magnitude of possible error. 50 ~ 210-site systems are used.

Fig. 23 Total energy under zero field as a function of m calculated with the TL-liquid wave function. For the half filling, where the TL-liquid state is reduced to the GWF, the value in the supersymmetric case is shown for an example. For $n = 1.0$ (0.5), a 102-(100-)site system is used. 5×10^4 samples are averaged.

Fig. 24 Comparison of magnetization curves for $n = 0.5$ and 1.0 . Symbols represent the

result of the variational functions. The optimized TL-liquid wave functions are used except for the supersymmetric case, in which the GWF is substituted. Solid line is the Bethe Ansatz result for $J/t = 2$.^{40,42)} Dotted line is the result for the non-interacting system. The result for the supersymmetric long-range t - J model is shown by dashed line.^{46,32)}

Fig. 25 (a) Charge and (b) spin susceptibilities calculated with Gutzwiller Approximation for the Hubbard model as a function of electron density for some values of U/U_c . Inset in (a) represents χ_c vs. U/U_c for the half filling. The 1D cosine band is assumed.
